This approach is hampered by the fact that the location of gene that is relevant to complex diseases is unknown. To address this problem, it has been proposed that it is useful to map complex diseases to the human genome using linkage data from pedigrees where affected individuals are relatives. Since 1995, a variety of statistical models have been proposed for this purpose. These models provide formal statistical tests for linkage. However, these tests have major disadvantages, including the fact that they only provide statistical evidence for or against linkage in a given region, not the true genetic location of the gene. False positive and false negative linkage results are possible. Another problem with current methods is that they are not designed to estimate the parameters that describe the data. Simulations show that the test statistics used by current methods are oversensitive to the true genetic location of the disease locus, which makes the tests too liberal. Therefore, the tests are inefficient for finding a disease locus in close proximity to the actual disease locus. A new method is proposed to overcome these problems. This method is based on an approximation to a likelihood ratio test that accounts for all of the parameters that describe the data, including those that describe the true disease locus. This likelihood ratio test also accounts for the effects of ascertainment and of missing data. The method is applied to the quantitative trait locus (QTL) analysis of the National Heart, Lung and Blood Institute and Cancer Genetic Markers of Susceptibility (CAMP) study of schizophrenia. The goal of the CAMP study is to identify genetic factors that may be involved in the pathogenesis of schizophrenia. The amount of missing data 3da54e8ca3
